13. ABSTRACT (Maximum 200 words) <p>The objective of this work was the determination of the chemical composition of exhaust products from the firing of scaled down rocket motors at the Army Signature Characterization Facility at Redstone Arsenal, and the comparison of those results with component levels predicted by a selected computer model. Both real time and off-line sampling and analysis approaches were employed. Four types of propellant compositions were evaluated. CO levels ranged from 85 - 350 ppm, while particle concentrations ranged from 30 - 100 mg/m³. All of the airborne particles were in the inhalable range. For two of the propellants, airborne lead was greater than 10 mg/m³. For the predominantly perchlorate formulation, hydrogen chloride (HCl) levels were greater than 100 ppm. Particulate PAH levels were about a factor of 10 lower than that in outside ambient air particulate matter. The computer model predicted mole fractions for CO were typically 20 - 35%, except for the predominantly inorganic formulation. The model correctly predicted only minor amounts of ammonia and essentially no hydrogen cyanide. The accuracy of the predicted CO/CO₂ ratios was low for all but one of the formulations. A modification of the model accomplished by mathematically accounting for mixing of hot exhaust gases with ambient air brought the predicted CO/CO₂ ratio into greater agreement with that which was observed experimentally.</p>

GENERAL INSTRUCTIONS FOR COMPLETING SF 298

The Report Documentation Page (RDP) is used in announcing and cataloging reports. It is important that this information be consistent with the rest of the report, particularly the cover and title page. Instructions for filling in each block of the form follow. It is important to stay within the lines to meet optical scanning requirements.

Block 1. Agency Use Only (Leave blank).

Block 2. Report Date. Full publication date including day, month, and year, if available (e.g. 1 Jan 88). Must cite at least the year.

Block 3. Type of Report and Dates Covered. State whether report is interim, final, etc. If applicable, enter inclusive report dates (e.g. 10 Jun 87 - 30 Jun 88).

Block 4. Title and Subtitle. A title is taken from the part of the report that provides the most meaningful and complete information. When a report is prepared in more than one volume, repeat the primary title, add volume number, and include subtitle for the specific volume. On classified documents enter the title classification in parentheses.

Block 5. Funding Numbers. To include contract and grant numbers; may include program element number(s), project number(s), task number(s), and work unit number(s). Use the following labels:

C - Contract	PR - Project
G - Grant	TA - Task
PE - Program Element	WU - Work Unit Accession No.

Block 6. Author(s). Name(s) of person(s) responsible for writing the report, performing the research, or credited with the content of the report. If editor or compiler, this should follow the name(s).

Block 7. Performing Organization Name(s) and Address(es). Self-explanatory.

Block 8. Performing Organization Report Number. Enter the unique alphanumeric report number(s) assigned by the organization performing the report.

Block 9. Sponsoring/Monitoring Agency Name(s) and Address(es). Self-explanatory

Block 10. Sponsoring/Monitoring Agency Report Number. (If known)

Block 11. Supplementary Notes. Enter information not included elsewhere such as: Prepared in cooperation with...; Trans. of ...; To be published in... When a report is revised, include a statement whether the new report supersedes or supplements the older report.

Block 12a. Distribution/Availability Statement.

Denotes public availability or limitations. Cite any availability to the public. Enter additional limitations or special markings in all capitals (e.g. NOFORN, REL, ITAR).

DOD - See DoDD 5230.24, "Distribution Statements on Technical Documents."
DOE - See authorities.
NASA - See Handbook NHB 2200.2.
NTIS - Leave blank.

Block 12b. Distribution Code.

DOD - Leave blank.
DOE - Enter DOE distribution categories from the Standard Distribution for Unclassified Scientific and Technical Reports.
NASA - Leave blank.
NTIS - Leave blank.

Block 13. Abstract. Include a brief (Maximum 200 words) factual summary of the most significant information contained in the report.

Block 14. Subject Terms. Keywords or phrases identifying major subjects in the report.

Block 15. Number of Pages. Enter the total number of pages.

Block 16. Price Code. Enter appropriate price code (NTIS only).

Blocks 17.-19. Security Classifications. Self-explanatory. Enter U.S. Security Classification in accordance with U.S. Security Regulations (i.e., UNCLASSIFIED). If form contains classified information, stamp classification on the top and bottom of the page.

Block 20. Limitation of Abstract. This block must be completed to assign a limitation to the abstract. Enter either UL (unlimited) or SAR (same as report). An entry in this block is necessary if the abstract is to be limited. If blank, the abstract is assumed to be unlimited.

EXECUTIVE SUMMARY

The overall objective of the work described in this report is four-fold: to a) develop a standardized and experimentally validated approach to the sampling and chemical and physical characterization of the exhaust products of scaled-down rocket launch motors fired under experimentally controlled conditions at the Army's Signature Characterization Facility (ASCF) at Redstone Arsenal in Huntsville, Alabama; b) determine the composition of the exhaust products; c) assess the accuracy of a selected existing computer model for predicting the composition of major and minor chemical species; d) recommend alterations to both the sampling and analysis strategy and the computer model in order to achieve greater congruence between chemical measurements and computer prediction.

Analytical validation studies were conducted in small chambers at the Oak Ridge National Laboratory (ORNL), while the actual firings were conducted at Redstone Arsenal. Real time determination of selected species was performed by a variety of techniques, including non-dispersive infrared spectrometry, chemiluminescence, electrochemical monitoring, and optical scattering. Samples for analyses of trace constituents were collected from individual firings in the ASCF, and returned to ORNL for analysis, usually by gas chromatography/mass spectrometry. Four types of propellants were examined: a double base, a double base with 8% potassium perchlorate, one propellant which was predominantly ammonium perchlorate, and a minimum signature reduced smoke propellant, which was about two-thirds octahydro-1,3,5,7-tetranitro-1,3,5,7-tetrazocine (HMX). Small, 2x2 motors, containing 25 - 75 g of propellant, produced significant quantities of carbon monoxide (CO) and particles when fired into the 20 m³ chamber. CO levels ranged from 85 - 350 ppm. This is equivalent to reaching 2500 - 7500 ppm if a full scale motor was fired in a similarly sized enclosed environment. Particle concentrations ranged from 30 - 100 mg/m³. All of the airborne particles were in the inhalable range. For two of the propellants (the double base and the minimum signature), airborne lead was greater than 10 mg/m³. No ammonia or hydrogen cyanide was detected above 1 ppm. For the predominantly perchlorate formulation, hydrogen chloride (HCl) levels were greater than 100 ppm in the ASCF chamber. Because of the relatively high background levels observed, trace organic vapor phase constituents were difficult to accurately quantify. While a wide variety of trace constituents were observed, only a few were present at levels greater than a few ppbv. Compounds present at levels greater than 10 µg/m³ included benzene, methyl crotonate, toluene, and cyanobenzene. A number of PAHs and nitrofluorene were observed in the airborne particulate matter. However, the levels were about a factor of 10 lower than that in outside ambient air particulate matter at a military installation.

Computer modeling was performed with the NASA-Lewis CET-86 version. This approach obtains estimates of equilibrium concentrations by minimizing free energy. Mole fractions of major and minor species were estimated for a range of exit/throat area ratios. The predicted mole fractions for CO were typically 20 - 35%, except for the predominantly inorganic formulation. The model correctly predicted only minor amounts of ammonia

and essentially no hydrogen cyanide. Predicted mole fractions did not vary a great deal with such input parameters as exit/throat area ratios or small changes in the heats of formation of the various compositions. The accuracy of the predicted CO/CO₂ ratios was low for all but one of the formulations. In general, if the model were to be used in its present state for health risk assessments, it would be likely to over-estimate exposure to CO.

Probably the greatest limitation of the model is its inability to account for reactions after hot exhaust gases leave the rocket motor nozzle. For example, the model predicted no significant quantities of NO would be produced, yet such was measured at ppm levels on every burn. A modification of the model accomplished by mathematically accounting for mixing of hot exhaust gases with ambient air brought the predicted CO/CO₂ ratio into greater agreement with that which was observed experimentally. It seems likely that with the appropriate modifications to account for the roles of kinetically governed processes and the afterburning of exhaust gases, the model could make a more accurate prediction of the amounts of the major products. However, it seems unlikely for the system to be modifiable to the extent to which accurate predictions of toxic or carcinogenic species present at the ppbv level could be made.

ACKNOWLEDGEMENT

We wish to thank the following individuals for their assistance with this project:

Ms. B. J. McBride, of the NASA-Lewis Research Center, for provision of the computer model used in the project; Dr. Eli Freedman, for assistance with interpretation of the results of the computer modeling; Mr. L. B. Thorne and his staff, of the U.S. Army Redstone Arsenal, for the construction and firing of the 2x2 rocket motors, the provision of samples of the various propellants, and the use of the Signature Characterization Facility and chamber; Dr. Steve Hoke, of the U.S. Army Biomedical Research and Development Laboratory, for the use of the on-line hydrogen chloride measurement system, and Major John Young, of the U.S. Army Biomedical Research and Development Laboratory, for his patience, support, and technical assistance in a number of the aspects of this project.

I. OBJECTIVES

The overall objective of the work described in this report is four-fold: to a) develop a standardized and experimentally validated approach to the sampling and chemical and physical characterization of the exhaust products of scaled-down rocket launch motors fired under experimentally controlled conditions at the Army's Signature Characterization Facility (ASCF) at Redstone Arsenal in Huntsville, Alabama; b) determine the composition of the exhaust products; c) assess the accuracy of a selected existing computer model for predicting the composition of major and minor chemical species; d) recommend alterations to both the sampling and analysis strategy and the computer model in order to achieve greater congruence between chemical measurements and computer prediction.

II. BACKGROUND

Upon initiation of the Army's Health Hazard Assessment Program in 1983, the lack of information on the potential health hazards from weapons combustion products, to include rockets and missiles, became evident. Research to elucidate significant health effects of rocket and missile combustion products has been limited. Experiences with weapons systems such as ROLAND, VIPER, HELLFIRE, STINGER, and MLRS have resulted in the development of specific medical issues by the U.S. Army. Presumably, these issues will be addressed, in order to enhance the effectiveness of soldiers using such weapons. Requisite to addressing these issues is defining the chemical and physical nature of the combustion products.

Evaluation of rocket exhaust toxicity from Army missile and rocket systems has been directed towards a limited number of combustion products. Chemical species such as carbon monoxide, carbon dioxide, nitrogen, oxides of nitrogen, hydrogen chloride, sulfur dioxide, ammonia, lead, and copper are among those frequently evaluated. A USAMRDC study¹ has demonstrated more than one hundred chemical species in the combustion products of selected propellants. Many of the species represent potential health hazards even though the majority of those identified were at low levels. During the study, data were obtained for the Multiple Launch Rocket System's (MLRS) propellant by computer prediction and laboratory analyses. The combustion product was generated by burning the propellant in a small test motor. When the exhaust plume was vented into a chamber with an inert atmosphere, good quantitative data was obtained for twelve chemical species, and was in excellent agreement with theoretically computed values. In excess of fifty trace gas species also were qualitatively identified.

Various investigators have examined propellant and related combustion products generated in a variety of ways to include directly from a weapon or other equipment system¹⁻⁵, burning in a calorimeter or bomb⁶⁻⁹, personal and general area sampling in indoor firing ranges^{10,11}, and detonation or combustion in chambers or microcombustors^{2,14-17}. The methods of sampling and characterization also have been varied. Sampling has been done under atmospheric^{1,2,4,5,12,16}, and less than atmospheric^{1-3,8,9,13-15} conditions which provide a basis for comparing the relation between variables, such as, pressure and available

oxygen, on the composition of the combustion product. Sampling methods have been either direct and continuous, e.g., the method used by Goshgarian^{13,14} where the exhaust products of solid propellants were introduced directly into a mass spectrometer for analysis immediately following combustion, or by collection in a container or on a medium for subsequent analysis. The latter has involved cryogenic trapping, evacuated glass or stainless steel cylinders, and sorbent cartridges, filters, and condensation trains. Analytical methods to detect organics, gases, metals, and particulates have included gas chromatography (GC), gas chromatography-mass spectroscopy (GC-MS), titration, optical and infrared spectroscopy, scanning electron microscopy (SEM), x-ray emission and diffraction, and particle size analysis. Because of limitations with each sampling and analytical technique, several techniques must be employed simultaneously to optimize qualitative and quantitative characterization.

Computer models have been used to predict propellant ballistic properties to include the identity of the major chemical species contained in the combustion products^{1,3,5,17-19}. When compared with laboratory derived empirical data, the models tend better to predict the major species than the minor ones both qualitatively and quantitatively^{1,5,19}. The models predict the chemical species that occur at the nozzle of the rocket as the exhaust exits; however, afterburning changes the chemical content of the combustion product. Afterburning and incomplete combustion effects are not predicted by the models.

The approach taken in this study was to carefully validate real time analytical methods in chamber studies at Oak Ridge National Laboratory (ORNL) for as many of the major constituents as practical. The instrumentation for real time monitoring would then be transported to the ASCF for the firing of the scaled-down test motors. Vapor and particle phase samples for determination of trace organics and metal species would be returned for analysis. The Army Signature Characterization Facility (ASCF) has been used to determine the concentrations of major toxic species in propellant exhaust, e.g., carbon monoxide, carbon dioxide, hydrogen chloride, lead, aluminum oxide, and other nuisance particles²⁰. The facility is a 19.6 m³ walk-in, climatic chamber with temperature limits of -40° to 140°F and humidity control in the range of 20 to 100% relative humidity (RH). Typical operating parameters are 70°F and 60% RH. Designed as a smoke measurement facility, the ASCF has been adapted for the measurement of rocket motor signature and exhaust constituents. The facility serves as a large gas cell in which the exhausts of standard 2 x 2 motors can be measured by infrared spectroscopy (Fourier Transform Infrared Spectroscopy, FTIS). Ports in the ASCF allow sampling and measurement by other methods, e.g., air sampling pumps and direct reading instruments.

The results of the characterization studies were then to be compared with values predicted using the most recent version of a computer model developed by the Lewis Research Center of the National Aeronautics and Space Administration (NASA-Lewis). The model was then to be refined to the extent of available resources, in order to improve the predictive capability of the system.

Results of these studies are described in two parts. In Part 1, results of the chemical and physical characterization studies are described and discussed. In Part 2, results of the

computer modeling work are described. Comparisons with characterization data are performed, and recommendations for model improvement are made.

PART 1: CHEMICAL CHARACTERIZATION STUDIES

EXPERIMENTAL

The sampling and analysis methods used in this study have been described in detail in a previous report²¹, and are summarized in Table 1. An assortment of real-time analytical instrumentation was employed. However, resources were not available for the use of on-line mass spectrometric measurement, as such would have required periodic transport to the ASCF. Essentially, the approach taken was to first validate candidate analytical methods in small chambers (0.4 and 1.4 m³) at ORNL. Analytical measurements using real time instrumentation were made of target species in the presence of well defined quantities of other species. The extent to which these materials altered the response to the target species was noted, and corrections made when appropriate. For species which could not be determined in real time (usually trace organic vapor phase and particle phase species), samples would be taken at the actual burns to be conducted at the ASCF, and returned to ORNL for detailed chemical analysis. Following method validation for the propellant composition of interest, the sampling and analysis instrumentation was transported to the ASCF at Redstone Arsenal, and deployed for monitoring and sampling. Typically, between 2 and 3 firings of a test motor could be conducted during each 8-hour shift. Burns of the various propellant formulations took place between August, 1987 and December, 1989.

RESULTS AND DISCUSSION

The compositions of the various propellant formulations tested in this project are listed in Appendix A. Briefly, Composition D was a double-base propellant, comprised of approximately 50% nitrocellulose and about 40% nitroglycerine. Composition H was also a double base system, with approximately 8% by weight of potassium perchlorate added. Composition L was a formulation comprised of nearly 75% ammonium perchlorate, with the remainder being polyvinylchloride plastic and di (2-ethylhexyl) adipate. Composition Q was a minimum signature propellant, comprised of 66% HMX, and about 11% each of nitroglycerine and butane triol trinitrate. (A fifth motor, referred to as Composition X was fired only one time, and no modeling studies were applied to it.) (Note that the linkage between the propellant and the weapon systems for which they may be used is considered CLASSIFIED information. Those having need of this information should contact the COR listed on the title page of this document.) All of the propellants contained small amounts of metals. The motor size tested varied between ca. 24 - 75 g. This compares to a typical launch motor weight on an anti-tank weapon system of ca. 560 g.

Sampling of the exhausts was not without its difficulties. For example, for the first run of Composition D, the high volume particulate collector was placed inside the ASCF

chamber. However, the shock wave from the firing was sufficient to blow the filter media out of the holder. Thus, for subsequent runs, the sampler was placed outside the chamber and

Trace Particle Phase Organics	Collection on two-stage, high volume filter, analysis by high performance liquid chromatography and/or gas chromatography/mass spectrometry.

connected to it with the flexible plastic pipe. Also, on a latter run with "D," the force of the shock wave buckled the main chamber access door on the ASCF. For the final firing of "D," the nozzle was changed to force the propellant to burn over a longer period of time. This resulted in a considerable alteration in the exhaust composition (see Table 2).

Major Constituents

The observed exhaust major constituent concentrations in the ASCF are reported in Tables 2 - 5, along with various physical characteristics of the motors. The data is summarized in Table 6.

It is important to note that for those constituents determined in real time (ie, the gases), the concentrations listed represent peak concentrations. For gases, maxima were typically achieved within 30 seconds of the firing of the rocket motors. Presumably, maxima were achieved as the chamber contents were mixed by the fan mounted inside the chamber. Such was not always the case for the particulate phase species. For example, in Figures 1 and 2 are compared the time courses for some of the major exhaust products for firings of Composition D and H motors, from about 30 seconds following the firing onward. For Composition D, immediately after following the achievement of maximum concentrations, the constituent levels slowly decreased. While the same happened for Composition H vapor phase species, the particles were very slow to reach a maximum. Although particle

Figure 1. Time course of exhaust products post firing, Composition D.

Figure 2. Time course of exhaust products post firing. Composition H.

size differences between the two products were minimal (see below), it was speculated that the action of the fans could have stirred up larger agglomerates which settled immediately after firing, which eventually broke up to form smaller primary particles. Concentration reductions seemed most likely due to leaking of the chamber contents through door seals, bulkheads, etc. Particle concentrations decreased somewhat more rapidly than those of vapor phase constituents, probably due to settling.

No attempt was made to determine the concentrations of methane, hydrogen gas, or water vapor. For the former two species, quantitative measurements would be very difficult without the use of an on-line mass spectrometer, and such was not available for this work. Water vapor is one of the major components of the motor exhaust. The mole fraction predicted by the NASA-Lewis computer program typically is in the range of 20% (see below). However, the difficulty of making accurate determinations of water vapor concentration in a large chamber is considerable. For example, the maximum amount of hydrogen in any of the formulations listed in Tables A-1 - A-4 is sufficient to produce only 15 g of H_2O in the 20 m^3 ASCF chamber. This is comparable to increasing the concentration by at most 0.75 g/m^3 , to a concentration of ca. 11 g/m^3 at 60% relative humidity at 21° C. The addition of this amount of water vapor would increase the RH by 4%, as long as no change in the temperature occurred. Given that such small changes would be difficult to measure accurately, and that water vapor itself is no health hazard,

it was decided that determination of water vapor would be omitted from the measurements.

A determination of the carbon balance for the chamber indicates that the analytical measurements account for approximately 60% of the carbon in the formulation. For example, using the data in Table A-1 for Composition D, there are ca. 2.06 moles of carbon in the motor. Data from Run 5 of the "D" test indicates ca. 1.2 moles of C tied up as the oxides of carbon (CO and CO₂). The analysis of the vapor and particle phase organic constituents (see below) indicates that only a very tiny amount of C is tied up in the trace species. And even if all the non-metal material collected as particulates was pure carbon, such would only add ca. 26 mg/m³ of carbon, or about 0.043 moles. Thus, it would appear that a significant fraction of the carbon present in the motor itself (ca. 33%) is present in some form which is not amenable to conventional analyses. Without confirmatory data, the composition of such material would be highly speculative.

All of the formulations, despite the relatively small quantities of propellant fired in the chamber (ca. 1/7 to 1/20 of a typical size launch motor) produced substantial concentrations of carbon monoxide, ranging from a low of about 300 ppm/100 g of propellant for Composition Q, to a high of nearly 1400 ppm/100 g for Composition L. The amounts of carbon dioxide produced varied considerably, from more than a factor of 10 greater than the CO produced, to only about half the amount of CO produced. Only very small quantities of nitric oxide were produced, and no measurable amounts of nitrogen dioxide were produced. The latter is not surprising, since the production of NO₂ is dependent on the square of the NO concentration²². If the concentration of NO is low, significant amounts of the dioxide will not be produced in the first 10 minutes following the firing of the motor (the duration of time for which the ASCF was sampled for the oxides of nitrogen). Essentially, no ammonia or hydrogen cyanide was found at levels greater than 1 ppm. In the two formulations which contained perchlorates, measurable levels of hydrogen chloride were found. However, the observed levels were not proportionate to amount of perchlorate present. For example, while Composition L had about 8x more perchlorate in the formulation than Composition H, the levels observed in the chamber were about 100x larger. There were a number of metals found in the airborne particles resulting from motor firings. Copper, aluminum (as the oxide), lead, tin, chromium, and cadmium were all found in measureable amounts. Probably the lead and cadmium are of the greatest concern from a health risk standpoint. For both Compositions D and Q, lead was found to be present in the diluted exhaust at levels greater than 10 mg/m³.

In Table 7 are listed the particle size distributions of the exhaust products for the formulations studied. The mass median aerodynamic diameters (MMAD) were all less than 2 μ m, indicating that the particles remaining airborne long enough to be collected by the sampling method were capable of being inhaled. Although Composition D had a measurably bimodal distribution, the higher of the two MMADs was still less than 5 μ m. Particles from Composition L had a somewhat smaller MMAD than of the other formulations, but the breadth of the distribution was larger.

TABLE 7

**Particle Size Distribution
Rocket Exhaust Particulate Matter
Mean Values**

Mass Median Aerodynamic Diameter (MMAD) and Geometric Standard Deviation (σ_g)

<u>Composition</u>	<u>MMAD (μm)</u>	<u>σ_g</u>
D ^a	1.46	1.86
H	1.44	1.77
L	0.807	2.14
Q	0.96	2.4

^a Composition D had a definite bimodal distribution:
large particles had a MMAD of 3.6 microns, with $\sigma_g = 1.8$;
small particles had a MMAD of 0.47 microns, with $\sigma_g = 1.7$.

Trace Constituents

Trace organic vapor phase constituents present in the exhaust atmospheres were determined by collection of samples on multi-sorbent traps, followed by analysis by thermal desorption GC/MS. Because of the sensitivity of the method, collection of sufficient sample was not difficult. However, the background levels of vapors in the chamber were very high, and as a result, made it very difficult to discern quantities of vapors arising from the firing of the rocket motor. Despite the fact that the chamber was flushed with clean air between most firings, background levels of collected constituents on chamber blanks were substantial (see Table 8). This suggests that there may be significant off-gassing of volatiles from materials adsorbed on the surfaces inside the chamber. Accurate quantitative determination of the constituents identified was exceedingly difficult, because it required determining the difference between two large values. Also, the largest peak

in many of the samples was determined to be a mixture of hydrocarbons that were not resolved, even by high-resolution chromatography. These may be unburned, volatilized waxes used in the manufacture of the test motors. In Appendix B, in Tables B-1 through B-4, are listed the various trace organic vapor phase components identified and quantified in the exhaust. The data is summarized in Tables 9 - 12. In this case, mean quantities were reported only if the compound was observed in two or more of the traps analyzed from the firing of a specific composition and if the compound was present at a level 50% greater than the highest level reported for any blank collected during the series of firings. Several comments are in order. First, as stated above, it was very difficult to obtain a truly "clean" chamber atmosphere into which to fire the motors.

Table 8

CONCENTRATION OF SELECTED CONSTITUENTS IN CHAMBER BLANKS

Naphthalene	8.8		

Originally, it was believed that the siloxane compounds may have resulted from contamination of the multi-sorbent traps with a soap bubble solution which was used in measuring the sample flow rates in some of the earlier studies. (This potential for contamination has been confirmed by subsequent experiments in the laboratory). However, the siloxanes were also present in the blanks which were acquired in later experiments, in which only instrumental calibration of the flow rates were made. Thus, the siloxanes may be off-gassed byproducts of the detergents used to clean the chamber prior to the motor firings, or they may be true products of the propellant combustion. Significant amounts of siloxane have been seen in the vapor phases of several of the exhausts from various motors. In general, there appeared to be a greater variety of trace organics present in the vapor phase of the composition D and H exhausts. The fact that Composition L is predominantly inorganic probably contributes to this observation.

Table 13 summarizes the maximum observed concentrations of non-siloxane compounds found in the ASCF atmospheres for those constituents with levels greater than 10 $\mu\text{g}/\text{m}^3$ (ca. 3 ppbv for benzene). For example, the average concentration for benzene was 17.6

$\mu\text{g}/\text{m}^3$ or 5.4 ppb. Overall, the concentrations of these species were several orders of magnitude below the levels at which they are regulated for workplace exposures. One may conclude table 9

from this that the levels of trace organic vapor phase constituents are probably not of concern from a health risk standpoint under most conceivable use scenarios. Only by repeated firings from an enclosed space could these materials reach toxic levels. And before toxic levels of the organic vapor phase species was reached, CO levels would probably be lethal.

Determination of the higher molecular weight particulate-phase constituents proved difficult for the samples from the initial runs of Composition D (the first propellant studied). Because of filter clogging immediately following the firing of the test motors, the number of particles collected was very small. For example, the largest amount of sample collected on any of the initial runs was 40 mg. This was dispersed over a 4"-diameter Teflon-coated glass fiber filter. Initial GC analysis of the extracts indicated very low levels of hydrocarbons. Next, the extracts were subjected to GC/MS analysis with selected ion monitoring (SIM). SIM has the advantage of identifying species from selected characteristic ions, as opposed to using the entire ionic fragmentation pattern. Due to the small amounts of material collected on the filters, quantities detected in the particulate filter extracts were considerably below our normal detection limits for the target constituents. For that reason, in the preceding studies, the particulate collection system was modified to be a two-stage filter. This approach proved to be much more successful at collecting greater amounts of particles. In Table 14 are listed the polynuclear aromatic hydrocarbons (PAH's) determined in the exhaust particles collected from the firings of Compositions D, H, L, and Q. In addition, a comparison is also made between these levels and those determined for outside air at a military base. A few comments are in order. First, only data for particles collected in the coarse filters are reported. The fine filters collected very few particles (1 - 5 mg), and thus many of the levels determined are

at or near the instrumental limits of detection. Nitro-PAHs were determined only for Composition D and H exhausts. The levels

^a Data from Griest, et al., 1988

determined in these earlier studies were so low that a repeat of the complex analyses did not seem warranted. Despite the very low levels of PAH found in the particulates, the results are fairly consistent from sample to sample. The concentrations of a few selected PAHs in the particles of the Q exhaust were somewhat higher, but not by more than an order of magnitude. The only nitro-PAH which was identified consistently in the exhausts of the motors was 2-nitrofluorene, in the exhaust of Composition H. Its concentration ranged from ca. 30 - 60 ng/g. Most of the other PAHs identified and quantified in the exhausts were present at levels less than 1 $\mu\text{g/g}$. The outdoor air particulate sample with which a comparison is made was acquired outside a large motor pool building at Fort Carson, Colorado, in the mid-1980's as background data for another project supported by the USABRDL²³. A major contributor to the particulates in this sample was expected to be diesel- and gasoline-powered motor vehicle exhaust. The comparison indicates that, with the exception of 2-nitrofluorene, the PAH content of the rocket exhaust particulate is substantially less than (usually by a factor of 10 or so) that of outdoor air particulate matter found in a semi-urban setting at a military base. Also, the BaP content of the exhaust particulates is about half that of cigarette smoke particulate matter²⁴. Because of the relatively low concentrations of the PAH in the particle phase, the airborne concentrations of the PAHs are very low. For example, at the maximum particle concentration of $\sim 1 \text{ mg/m}^3$ in the ASCF chamber (as a surrogate for human exposure conditions), the highest observed airborne benzo(a)pyrene concentrations would be approximately $0.09 \mu\text{g/m}^3$, and that of benzo(g,h,i)perylene would be $0.36 \mu\text{g/m}^3$. At these levels, the airborne PAHs and nitro-PAHs in the rocket exhaust probably do not represent an additional health hazard above that of normal urban air particulates for the troops using such weapon systems.

SUMMARY AND RECOMMENDATIONS - PART 1

The exhaust products from the firing of 2x2 rocket motors in a 20 m^3 test chamber have been characterized. The data indicated that of all of the toxic and/or carcinogenic species present, most were present at very low levels. Of the major toxic constituents, carbon monoxide was the most universally present. Interestingly, the formulation with the greatest fraction of inorganic material (Composition L) yielded the highest concentration of CO in the ASCF chamber per 100 g of propellant. Nitric oxide was present in all of the exhausts, but typically at levels less than 5 ppm in the 20 m^3 chamber. No ammonia or hydrogen cyanide was observed at levels greater than 1 ppm. Levels of HCl were observed in the Composition L exhaust which were very high ($> 100 \text{ ppm}$), and it seems likely that firing of this propellant in an enclosed space would produce very high concentrations of this toxic species. However, no data was obtained as to whether the HCl was present in the particle or the vapor phase.

Particles were present at substantial levels in all of the exhaust atmospheres ($\geq 30 \text{ mg/m}^3$). Particle size distributions indicated that for those particles which could be collected under the sampling conditions employed, virtually all of the material was within an inhalable size range ($< 10 \mu\text{m}$ mass median diameter). A large fraction of the airborne particles were comprised of metallic species. Copper and lead (especially the latter) were present in the ASCF atmospheres of many of the motor types at levels above those regulated by OSHA.

However, the levels of PAHs and nitro-PAHs in the particulates were very low. Comparison with airborne particulate matter collected at a military installation indicated that the PAH content of the particles was about 1/10 that of outdoor air particles.

Quantitative determination of the organic vapor phase constituents was very difficult due to both the very low levels at which they were present and the presence of large amounts of other species in the background samples. The latter included a large number of cyclosiloxanes, probably from the off-gassing of the chamber walls following cleaning. Only a few exhaust components were found at levels greater than a few ppb. These included benzene, toluene, methylcrotonate, and cyanobenzene. These were typically present at levels less than 10 ppb in the chamber.

From the standpoint of follow-on studies, recommendations depend on the goal of such efforts. If the goal is to refine the comparison between the observed chemistry and the predicted compositions, then the determination of methane (CH_4) and molecular hydrogen (H_2) would be very desirable. Such is a very difficult task, and would likely require a dedicated real time mass spectrometer to make such measurements. However, the determination of such constituents would not significantly further the understanding of potential health risks of the exhaust products, since neither are toxic species.

Since these experimental studies were performed, there have been two developments in the field of analytical chemistry which, if applied to these studies, could significantly improve the quality of the data generated, especially with regard to the determination of volatile organics. First, a number of carbon based adsorbents are now commercially available which have many fewer artifacts than the Tenax used in these studies. Were the sorbent traps used in these studies replaced with the new systems, it is likely that the number of artifacts present in the samples would be significantly reduced, minimizing the complexity of the interpretation of the data. Also, the recent development of direct sampling ion trap mass spectrometry (DSITMS) for the determination of airborne vapor phase constituents is significant. DSITMS could be used to provide determination of a number of volatile species of toxicologic interest in real time, much like an NDIR analyzer provides real time measurement of CO or CO_2 . Transportable DSITMS systems are now under development at ORNL for air toxics monitoring at environmental remediation sites, and such technology could be useful for other scenarios.

Finally, the most important recommendation for future work is the determination of the exhaust product composition under actual field conditions, firing full scale motors. There are two important reasons for this. First, the data in this study indicates that changes in the physical properties such as burn time can have a radical effect on exhaust composition. This suggests that it will be difficult to obtain highly realistic data unless true field measurements can be made. Secondly, firing of the test motors in an enclosed chamber causes significant run-to-run background contamination problems. Perhaps the firing of motors in single use, disposable structures, such as large nylon tents, would eliminate much of the contamination problem.

PART 2 - MODELING FOR HEALTH HAZARD PREDICTION

INTRODUCTION

Over the past 30 years, several digital computer programs have been developed at the National Aeronautics and Space Administration's Lewis Research Center to carry out the considerable numerical calculations involved in the determination of the equilibrium composition of complex chemical mixtures at high temperatures^{25, 26, 27}. Updates to these programs have incorporated improved computational methods and adaptations to improvements in computer speeds and capacities. In accordance with a suggestion from project management, we have used the 1986 version²⁸ of the program described in Reference 27 to obtain estimates of the composition of the exhaust gases from four different solid propellants. This was referred to as the NASA-Lewis model, version CET-86. The program obtains estimates of the equilibrium composition of a mixture of several components by minimizing either the Gibbs function or the Helmholtz function. If temperature and volume are constant, the Helmholtz function of a system decreases during an irreversible process, becoming a minimum at equilibrium; if temperature and pressure are constant, the same is true of the Gibbs function²⁸. All gases are assumed to be ideal, even if small amounts of condensed species are present. Calculations can be done for any one of six combinations of assigned state parameters (e.g., temperature, pressure, density, entropy, and enthalpy); additionally, theoretical rocket performance data can be obtained. The assumptions involved in the calculation of rocket performance parameters are listed in Ref. 3. Briefly, they are: (1) validity of the one-dimensional form of the continuity, energy, and momentum equations; (2) zero velocity (no gas movement) in the combustion chamber; (3) complete combustion (in the sense that all reactants are converted to products); (4) adiabatic combustion; (5) isentropic (adiabatic and reversible) expansion; (6) homogeneous mixing; (7) ideal gas law; and (8) zero temperature and pressure lags between condensed and gaseous species. An extensive discussion of these assumptions and their validity can be found in Reference 30.

The program first determines combustion properties in the rocket motor chamber and then determines exhaust composition and properties at various stations in the nozzle. Since our propellants were fired in motors having a range of exit diameters, we used the feature of the program that allows estimation of exit compositions for a set of several exit to throat area ratios. (In this case, the throat of the motor is considered to be the choke point, or opening of the smallest diameter. The exit is the exit of the motor nozzle. Using these definitions, the ratio of the exit:throat areas, A_e/A_t , must always be larger than 1.0.) In Table 15 are listed the ranges of exit/throat area ratios possible for each motor. In each of the predictions, we used the design pressure as the combustion chamber pressure. The throat pressure is defined to be the pressure at which the flow velocity is equal to the velocity of sound.

The iterative procedures used by the program are discussed in detail in Reference 27. Briefly, combustion temperature and equilibrium compositions are determined for an

* These are estimated exit diameters. Actual exit diameters varied between 0.75 and 1.25 inches.

assigned chamber pressure and the reactant enthalpy. From the combustion compositions and temperature, the combustion entropy can be determined. Assuming isentropic expansion, the program then obtains a first estimate for the ratio of chamber pressure to throat pressure; from the throat pressure and the entropy, the actual gas velocity, the speed of sound, and the Mach number can be calculated; if the Mach number is not sufficiently close to unity, the pressure ratio is corrected and a further calculation of Mach number is done. Exit conditions for assigned exit-to-throat area ratios are also obtained from an initial estimate of the ratio of the chamber pressure to the exit pressure, followed by iterative correction. The converged value of pressure ratio for each area ratio is used as the initial estimate for the next area ratio.

We obtained the program, test case input, and output from the NASA Lewis Research Center²⁸. We were able to compile the program on our VAX 6000-420 computer and were able to reproduce the test case output with no problems. In our series of calculations the program has performed in a very reliable manner; we have had no difficulties with any of the iterative procedures failing to converge.

RESULTS AND DISCUSSION

In Tables 16 - 19 are listed the predicted mole fractions of various exhaust components over the range of potential ratios of exit areas to throat areas. (The full computer printouts for selected runs for each composition are included in Appendix C.) Note that there have been two independent checks of these computations³¹. First, CET86 computations of mole fractions of Composition H were checked against the "Blake" code and found to be in excellent agreement. (See discussion regarding Table 23, below). Secondly, the calculations were verified by running MUCET, a modified version of CET86 prepared by Eli Freedman & Associates for use with microcomputers. Results were identical to those reported here.

The model has a cut-off feature. Essentially, it can predict the levels of over 100 compounds, but will only report out those mole fractions which are larger than a user-specified value. For this work, a mole fraction of 5×10^{-7} was employed. The rationale for using this value was as follows. If it is assumed that there are about 2 moles of exhaust products in the ASCF chamber following a firing, a mole fraction of 5×10^{-7} would be equivalent to 1×10^{-6} moles of the particular product in the chamber. This assumption was in fact supported by the chemical characterization data (see above). For a compound with a nominal molecular weight of 100 g/mole, this translates to a concentration of $5 \mu\text{g}/\text{m}^3$, or 1.5 ppbv, in the 20 m^3 ASCF chamber. Few airborne compounds are considered to be a significant health risk at such low concentrations. In addition, unless a very large sample is acquired, it is usually difficult to confidently quantify such species at these low levels.

Using this criterion, with the exception of the metals in the exhaust products, the only compounds which were predicted to be present in the exhaust were carbon monoxide, carbon dioxide, hydrogen, water vapor, ammonia, and methane. In none of the cases did the model predict significant quantities of nitric oxide, despite the fact that NO was observed at levels near to or greater than 1 ppm on each burn.

A_e/A_t: Ratio of the exit area to throat area

For many of the input parameters, the model was not particularly sensitive to substantial changes. For example, for Composition H, a nearly 3-fold change in the exit/throat area ratios decreased the predicted mole fraction of CO by less than 12%. The ratio of major components was not significantly altered. For Composition D, a 5-fold change in the A_e/A_t reduced the CO/CO₂ ratio by 35%. The ratios of minor to major components were typically affected to a greater degree. In many cases, mistakes made in the original entry of data into the model were difficult to identify, since the mistaken or modified entry resulted in such a small change in the data output. For example, considerable effort was placed into obtaining or calculating the best heats of formation for compounds present in the formulations. However, an exact value may not be particularly critical to the modeling projections. For example, in Table 20 are compared the mole fractions predicted by the model for a $\pm 5\%$ change in the heat of formation of ammonium perchlorate, which comprises nearly 75% of the starting formulation. The results of the manipulation show only minor changes in the predicted mole fractions. For example, the predicted mole fraction of HCl changed only in the fourth decimal place.

From the standpoint of predicting the composition of the exhaust products in the chamber, the model was not particularly effective. As stated previously, in no case did the model predict NO to be present at levels above 10 ppb, even though NO levels were experimentally observed near 1 ppm. In Table 21 are compared the ranges of observed and predicted ratios of carbon monoxide to carbon dioxide in the ASCF chamber. For Composition H, the predicted values were very close to those observed. For Composition L, the model was accurate to within a factor of 2 - 3. For the other two formulations tested, there was substantial disparity between observed and predicted values. In both of these cases, the model predicted a much higher fraction of CO to be present than that which was observed. If the model had been used to make a health risk projection, the risk from CO exposure would have been considerably overestimated.

The comparison of observed and predicted absolute concentration levels in the ASCF chamber is a much more complex task. Briefly, the moles of the elements present in the formulation were computed. Since we did not determine water vapor or hydrogen gas in the chemical characterization studies, it was assumed that all of the H present in the formulation was converted to water vapor. (From a functional standpoint of predicting the concentrations of other species, it makes no difference if the H present existed as water vapor or H₂ gas.) Next, the total number of moles measured in the chamber was calculated, assuming 100% efficiency of conversion of H to water in the chamber. Finally, the mole fractions of the various species were multiplied by the total number of moles present, and divided by the chamber volume, in order to estimate chamber concentrations of the target species. The results of these calculations are summarized in Table 22. In general, the model was very good at predicting the concentrations of metallic species. In the case of zirconium oxide for Composition Q, and copper for Composition D, there was substantial over-estimation of the concentrations. This may be due to settling of particulates containing

these species before they could be collected. For Compositions D and Q, the model substantially over-predicts CO and underestimates the amount of CO₂ produced. In the cases of the formulations which were expected to produce measurable amounts of HCl, the model predicted more HCl than was measured in both cases. It could be that in this case, the acquisition of the sample could be suspect. First, some of the HCl or potassium chloride could have been adsorbed on particulate matter which settled very rapidly in the chamber. In this case, the material would not reach the input to the continuous HCl analyzer. In addition, some of the HCl may have been lost in the short lengths of Teflon tubing leading from the chamber atmosphere to the analyzer.

In terms of the trace organic vapor and particle phase constituents, the model correctly predicts that the concentrations of these species will be low. In fact, the observed levels of such species as benzene and benzo(a)pyrene were much less than 100 ppbv, or 1 µg/m³, respectively. However, the number of toxic species which the model considers is limited, and it is certainly conceivable that a compound not considered by the model could be present at sufficiently high levels to warrant some health risk consideration.

LIMITATIONS AND MODIFICATIONS

In addition to not considering all of the toxic species likely to be produced by the ignition of a predominantly organic matrix, the model does have several limitations. First, it is an equilibrium based system, and does not take into account those synthesis pathways which

may be governed predominantly by kinetic processes. Secondly, it assumes ideal gas behavior on the part of all of the gases produced. This assumption is not likely to be accurate over the entire range of conditions existing inside the rocket motor. However, from a practical standpoint, this may not be a severe limitation. For example, the magnitude of non-ideal gas effects depends primarily on the density and the temperature in the system. For the system in question, the largest densities occur in the chamber. Interestingly, the most dense gas (H), has a density of only 0.037 g/mL, which is not sufficiently large to induce substantial deviations from the ideal gas law. To illustrate this point, Freedman³¹ has used the "Blake" code to compute chamber concentrations (at 340.23 atmospheres pressure and a temperature of 3167° K) assuming both ideal and real gas equations of state. This was performed for Composition H, whose exhaust products were capable of reaching some of the higher temperatures in the study. The results are listed in Table 23. It is clear that the differences between the real and the ideal gaseous equations of state are very small. And although there are differences between the NASA-Lewis results and those from the "Blake" code, the differences are negligible from a practical standpoint and are due to differences in the thermodynamic data bases themselves.

Finally, and probably most importantly, the model assumes that all of the chemical processes are frozen at the point at which the exhaust gases exit the motor. There is a considerable body of evidence to suggest that this is not the case. For example, the model predicts that no significant production of NO will occur for any of the formulations tested. However, NO was in fact observed. We believe that its presence is due to the effect of the heated exhaust gases on the ambient air in the chamber. That is, the heat from the motor firing causes the formation of nitrogen monoxide. The production of NO is probably proportional to the duration of the flame contact with the air. For example, during run No. 5 for Composition D, the shock wave from the firing of the motor caused some damage to the chamber. A different nozzle was installed on the test motor used for burn #6. This lengthened the burn time, and reduced the pressure of the burn. Such resulted in some substantial differences between burns #5 and #6 for the Composition D motors. The change in the NO concentration is considerable. Probably, the increase in time that the flame is in contact with the air causes much more NO to be produced. Note also the change in the CO concentration from Run No. 5 to Run No. 6.

Following consultations with Dr. Eli Freedman, we decided to test the hypothesis that including a step in the computer calculations which would determine the influence of mixing the predicted exhaust gases with ambient air would lead to a more accurate prediction of the observed gas concentrations in the chamber. The model was revised to mix the exhaust gases with the ambient air at fixed ratios and at varying pressures and temperatures. As an example, the exit composition from propellant D (a formula which had initially yielded a relatively inaccurate prediction of the observed CO/CO₂ ratio) was selected as a "fuel" which could be mixed with air. Initial exit pressure and temperature were set at 39.5 atmospheres and 1837 °K, respectively. The "fuel" was mixed with ambient air in the ratios given in Table 24 to yield equilibrium compositions at two arbitrarily selected lower pressures. As indicated in Table 24, there was a substantial decrease in the CO/CO₂ ratio. The resulting ratio is much closer to that which was

observed experimentally than the ratio predicted by the unmodified model, suggesting that there is considerable mixture with ambient air and conversion of carbon monoxide to carbon dioxide between the vicinity of the motor exit and the analysis train. That the model does not consider the influence of mixing with ambient

^aFrom Reference No. 30

air on the products of propellant firing has been observed by other investigators³². Snelson, et al. reported that double base propellants fired in Argon atmospheres produced mole fractions of CO which were much closer to those predicted by thermodynamic modeling than when the same propellants were fired in ambient air.

Table 24

Influence of Exhaust Gas Mixing with Air
on Carbon Monoxide/Carbon Dioxide Ratios

Composition D

	Fuel/Air = 5*		
Pressure, atm	39.5	5.0	1.0

CO/CO ₂	0.31	0.25	0.17

* Considers exhaust gases from motor nozzle as "fuel."

RECOMMENDATIONS FOR FURTHER WORK

It would be interesting to compare these results with other computer models. Software is available with similar, but not identical methods of computation and data fitting³³.

It may be possible to extend the NASA Lewis model to account for nonideal gas equations of state for some of the major components, without involving major modifications to the program. However, any revision is not to be undertaken lightly; the program is some 5000 lines of Fortran and represents a very large investment of time and effort. The development of a new model would require a similar investment.

A thorough review of the thermal and transport property data base may seem to be desirable, in order to incorporate any new information available since the 1986 revision, and to have some additional assurance that the data have been entered correctly. However, there have only been 8 changes to the data base, and none have practical significance for this study³¹. And since transport properties are not a significant factor in this work, any changes should not have an effect on the conclusions.

It would be useful to model the chemical kinetics of these processes, using the software described in Reference 34. It should be noted, however, that a considerable amount of effort would be required to elucidate the reactions occurring in these events and to make estimates of the necessary rate constants. The Arrhenius constants and the activation energies for the hundreds of conversions processes are not available. In contrast, modeling the flow processes may be useful, since it could lead to a better understanding of the amount of air entrained with the exhaust during combustion.

It might be useful to do some experimental firings of the motors into inert atmospheres, such as argon, in order to test the air mixing hypothesis. However, such in and of itself would not aid in the refinement of the model.

Finally, alternatives to the "air entrainment" explanation as the source of disagreement between experiment and computation should be explored. For example, calculations described in this report were carried out for two possible cases: either the chemical reactions in the expanding flow from the combustion chamber maintain complete equilibrium from throat to the nozzle exit, or else the flow is completely frozen once it leaves the nozzle throat. But the intermediate case is also possible. That is, the flow may freeze somewhere between the throat and the exit. This could provide a possible explanation for the discrepancy between experiment and computation without requiring the assumption of entrained air. To implement such an approach, an adiabatic expansion calculation should be run. Initial estimates provided to the authors of this report suggest that this approach is feasible³¹. However, to take full advantage of such an approach, careful experimental determination of hydrogen and methane would have to be performed. Because of the complexities of such real time analyses, these measurements could not be performed.

Appendix C

**Output from Selected Runs of Computer Model
NASA-Lewis CET-86**

Table C-1
NASA - Lewis CET - 86
Output
Composition D

1. The first part of the document is a title page. It contains the title "The Role of the State in the Development of the Economy" and the author's name "John Doe".

2. The second part of the document is an abstract. It summarizes the main points of the paper, including the role of the state in the development of the economy.

3. The third part of the document is the introduction. It discusses the importance of the state in the development of the economy and the role of the state in the development of the economy.

4. The fourth part of the document is the main body of the paper. It is divided into several sections, each discussing a different aspect of the role of the state in the development of the economy.

5. The fifth part of the document is the conclusion. It summarizes the main findings of the paper and discusses the implications of the findings.

6. The sixth part of the document is the bibliography. It lists the sources used in the paper.

7. The seventh part of the document is the appendix. It contains additional information related to the paper.

8. The eighth part of the document is the index. It lists the pages on which the topics discussed in the paper are mentioned.

9. The ninth part of the document is the list of figures. It lists the figures included in the paper.

10. The tenth part of the document is the list of tables. It lists the tables included in the paper.

11. The eleventh part of the document is the list of references. It lists the references used in the paper.

12. The twelfth part of the document is the list of footnotes. It lists the footnotes included in the paper.

13. The thirteenth part of the document is the list of appendices. It lists the appendices included in the paper.

14. The fourteenth part of the document is the list of indices. It lists the indices included in the paper.

15. The fifteenth part of the document is the list of figures. It lists the figures included in the paper.

16. The sixteenth part of the document is the list of tables. It lists the tables included in the paper.

17. The seventeenth part of the document is the list of references. It lists the references used in the paper.

18. The eighteenth part of the document is the list of footnotes. It lists the footnotes included in the paper.

19. The nineteenth part of the document is the list of appendices. It lists the appendices included in the paper.

20. The twentieth part of the document is the list of indices. It lists the indices included in the paper.

.....

A 10x10 grid of dots forming the letters 'A', 'D', 'E', 'E', 'A' in a stylized font. The letters are arranged in a single row, with each letter occupying approximately 2 units in height and 2 units in width. The dots are black on a white background.

.....
